# Timer Reconsideration for Enhanced RTP Scalability

**Abstract**

RTP, the Real Time Transport Protocol, has gained widespread acceptance as the transport protocol for voice and video on the Internet. Its companion control protocol, the Real Time Control Protocol (RTCP), is used for loose session control, QoS reporting, and media synchronization, among other functions. The RTP specification describes an algorithm for determining the RTCP packet transmission rate at a host participating in a multicast RTP session. This algorithm was designed to allow RTP to be used in sessions with anywhere from one to a million members. However, we have discovered several problems with this algorithm when used with very large groups with rapidly changing group membership. One problem is the flood of RTCP packets which occurs when many users join a multicast RTP session at nearly the same time. To solve this problem, we present a novel adaptive timer algorithm called reconsideration. We present a mathematical analysis of this algorithm, and demonstrate that it performs extremely well, reducing the congestion problem by several orders of magnitude. We also back up these results with simulation.

## 1 Introduction

There has recently been a flood of interest in the delivery of multimedia services on the Internet. The growing popularity of Internet telephony, streaming audio and video services (such as those provided by Real Audio) and the Mbone are all indicators of this trend. To support these applications, standards are being developed to insure interoperability. These include the ITU-T H.323 [1] specification for Internet telephony, the Session Initiation Protocol (SIP) [2] for multimedia session initiation, and RTSP [3] for controlling multimedia servers on the Internet.

Interwoven with all of the above protocols is the Real Time Transport Protocol (RTP) [4]. It is used by H.323 terminals as the transport protocol for multimedia; both SIP and RTSP were designed to control multimedia sessions delivered over RTP. Its main function is to carry real time data, such as voice and video, over an IP network. To do this, RTP packets contain payload type identifiers, sequence numbers, end-of-frame markers, and timestamps, all of which aid in synchronization, loss detection, and identification. RTP also contains a control component, called the Real Time Control Protocol (RTCP). It is multicast to the same multicast group as RTP, but on a different port number. Both data senders *and* receivers periodically multicast RTCP packets. RTCP packets provide many services. These include participant identification (via the Source Descriptor (SDES) packet), QoS reporting from receivers, and sender reports for inter-media synchronization. This information is key for sender-based rate adaptation [5], network monitoring [6], and conference control.

Since RTP was designed for multicast, it was engineered to work well with both small sessions (such as a 5 party teleconference) and large ones (such as an Mbone broadcast of a shuttle launch, where group sizes of two hundred listeners have been reported [7]). As the demand for multimedia continues to grow, Mbone sessions with thousands of members will become commonplace. It has even been suggested that RTP might be the transport protocol of choice for multicast distribution of multimedia in future cable networks, where tens of thousands of users might be the norm.

The principle difficulty in achieving scalability to large group sizes is the rate of RTCP packet transmissions from a host. If each host sends packets at some fixed interval, the total packet rate sent to the multicast group increases linearly with the group size, $N$. This traffic would quickly congest the network. To counter this, the RTP specification requires that end systems utilizing RTP listen to the multicast group, and count the number of distinct RTP end systems which have sent an RTCP packet. This results in a group size estimate, $L$, computed locally at each host. The interval between packet transmissions is then set to scale linearly with $L$. This has the effect of giving each group member (independent of group size) a fair share of some fixed RTCP packet rate to the multicast group.

The above scaling mechanism works well for small to medium sized groups (up to perhaps a few hundred members). However, it suffers from problems when applied to larger groups, particularly ones whose group membership is dynamic. We have identified three inter-related problems which arise with large, dynamic multicast groups.

The first difficulty is congestion. In many cases, the access bandwidths for users will be small compared to network bandwidths (28.8 kb/s modems, for example, can now handle multimedia RTP sessions when RTP header compression [8] is used). We also anticipate that many multicast RTP sessions will exhibit rapid increases in group membership at certain points in time. This can happen for a number of reasons. Many sessions have precise start times. Multimedia tools such as vat and vic can be programmed to join a session at the instant of its inception. Even without automation, users are likely to fire up their applications around the time the session is scheduled to begin. Such phenomena are common in current cable networks, where people change channels when shows begin and end. Studies have been performed to look at the group membership over time of some of the popular sessions on the Mbone [9][7]. These studies show exactly this kind of "step-join" behavior. The result of these step joins are inaccuracies in the group size estimates obtained by listening to the group. Each newly joined member believes that they are the only member, at least initially. They send RTCP packets at their fair share of the RTCP bandwidth (which each believes is all of it). Combined with slow access links, the result is a flood of RTCP reports, causing access link congestion and loss.

A second problem for RTCP scalability is *state storage*. In order to estimate group sizes, hosts must listen to the multicast

0-7803-4383-2/98/$10.00 © 1998 IEEE.

group and count the number of distinct end systems which send an RTCP packet. To make sure an end system is counted only once, its unique identifier (SSRC) must be stored. Clearly, this does not scale well to extremely large groups, which would require megabytes of memory just to track users. Another difficulty is *delay*. As the group sizes grow, the time between RTCP reports from any one particular user becomes very large This interval may easily exceed the duration of group membership. This means that timely reporting of QoS problems from a specific user will not occur, and the value of the actual reports is lost.

In this paper, we consider only the first problem, that of *congestion*. It is our aim to solve this problem with a *single mechanism, applicable to large groups and small alike*. This means that the use of summarizers [10] is not considered, for example, since this solution makes sense for large groups only.

There has been a small amount of prior work on resolving difficulties with timers in Internet protocols. Most prominent among this work is [11] and [12]. Sharma et. al. consider how to scale soft state timers to varying link capacities and state quantities. Their work considers only the point to point case. Our work considers the case where the network state is distributed among many nodes, connected by some sort of broadcast mechanism. Our work can thus be viewed as a generalization of their's to distributed multicast groups. As such, our algorithm for controlling the congestion problem in RTP is applicable to other protocols and systems. An extension to the Service Location Protocol [13] has been proposed [14] which uses the reconsideration algorithm to control congestion in the multicast group used to disseminate information on network services. The algorithm is generally applicable to distributed systems where (1) control of bandwidth is desirable, (2) the bandwidth is used to transmit state, (3) the state is used to determine end system transmission rates, and (4) the state is dynamic. These constraints apply to BGP [15], for example, when a route server is used and update rates are to be controlled.

## 2 Current RTCP Algorithm

Each user $i$ in a multicast group using RTP maintains a single state variable, the *learning curve*, which we denote by $L(t)$. This variable represents the number of other users that have been heard from at time $t$. The state is initialized to $L(0) = 1$ when the user joins the group.

Each user multicasts RTCP reports periodically to the group. In order to avoid network congestion, the total rate of RTCP reports multicast to the group, summed across all users, is set at 5% of the total multicast session bandwidth (it is assumed in RTP that this quantity is known a priori). We define $C$ as the average interval between arrivals of RTCP packets (from any user) at end-systems. $C$ is then given by the average RTCP packet size divided by 5% of the session bandwidth. To meet this criteria, each user computes a *deterministic interval*, which represents the nominal interval between their own packet transmissions required to meet the 5% constraint. This interval is given by [1]:

$$T_d = \max(T_{\min}, CL(t)),$$

where $T_{\min}$ is 2.5 s for the initial packet from the user, and 5 s for all other packets. To avoid synchronization, the actual interval is then computed as a random number uniformly distributed between 0.5 and 1.5 times $T_d$.

The algorithm for sending RTCP packets follows directly. Assume a user joins at time $t = 0$. The first packet from that user is scheduled at a time uniformly distributed between $1/2$ and $3/2$ of $T_{min}$ (which is 2.5 s for the first packet), putting the first packet transmission time between 1.25 and 3.75 seconds. We denote this time as $t_0$. All subsequent packets are sent at a time $t_n$ equal to:

$$t_n = t_{n-1} + R(\alpha)\max(5, CL(t_{n-1})), \quad (1)$$

where we have defined $R(\alpha)$ as a random variable uniformly distributed between $(1-\alpha)$ and $(1+\alpha)$. ($\alpha$ equals $1/2$ in the current algorithm; we generalize because $\alpha$ has a strong impact on transient behavior).

The difficulty arises when a large number (say, $N$) of users all join the group at the same time. We call this a *step-join*. Since all users start out with $L(t) = 1$, all schedule their first packet to be sent between $t = 1.25$ and $t = 3.75$, a fixed, 2.5 second interval. The result is a flood of $N$ packets for 2.5 s, many of which are lost if the access bandwidth is low. Since group size estimates are based on the reception of these packets, losing them will continue to cause each user to have a low estimate of the actual group size. This will cause continued congestion until enough packets get through to make the group size estimates correct.

The flood of packets caused by the current RTCP algorithm with a step join has both good and bad consequences. The rapid arrival of RTCP packets causes a quick convergence to the correct group size estimate, which is good. However, the real packets of interest are the RTP media packets, not the RTCP packets. Because of the restricted amount of bandwidth available at many access links, we believe that maintaining the RTCP rate at 5% of the session bandwidth is the goal of any fix for the flooding problem.

## 3 Reconsideration

Our contribution is a new algorithm which we call *reconsideration*. The effect of the algorithm is to reduce the initial flood of packets which occur when a number of users simultaneously join the group. This algorithm operates in two modes, conditional and unconditional. We first discuss conditional reconsideration.

At time $t_n$, as defined above, instead of sending the packet, the user checks if the group size estimate $L(t)$ has changed since $t_{n-1}$. If it has, the user *reconsiders*. This means that the user recomputes the RTCP interval (including the randomization factor) based on the current state (call this new interval $T'$), and adds it to $t_{n-1}$. If the result is a time before the current time $t_n$, the packet is sent, else it is rescheduled for $t_{n-1} + T'$. In other words, the state at time $t_n$ gives a user potentially new information about the group size, compared to the state at time $t_{n-1}$. Therefore, it redoes the interval computation that was done previously at time $t_{n-1}$, but using the new state. If the resulting interval would have caused the packet to be scheduled before the current time, it knows that its interval estimate was not too low. If, however, the recomputation pushes the timer off into the future, it knows that its initial timer estimate was computed incorrectly, and it delays transmission based on its new timer.

[1] In actuality, the RTP specification allocates 75% of the RTCP bandwidth to data senders, and the remaining 25% to listeners. In the remainder of the paper, we assume that everyone is a listener. This simplifies the analysis and simulations, all of which can be trivially extended to include the case where there are senders.

Intuitively, this mechanism should help alleviate congestion by restricting the transmission of packets during the convergence periods, where the perceived group sizes $L(t)$ are rapidly increasing.

In unconditional reconsideration, the user reconsiders independently of whether the number of perceived users has changed since the last report time. Thus, the RTCP interval is always recomputed, added to the last transmission time $t_{n-1}$, and the packet is only sent if the resulting time is before the current time. Clearly, when the group sizes are increasing, this algorithm behaves identically to conditional reconsideration. However, its behavior differs in two respects. First, consider the case where group size estimates have converged, and are no longer changing. In conditional reconsideration, no timer recomputation is done. But for unconditional, it is still redone. Since group sizes have not changed, the deterministic part of the interval remains the same. However, the random factor is redrawn each time. This means that packets will be transmitted when the recomputed random factor is smaller than the previous factor, and packets will be delayed when the recomputed random factor is greater than the previous one. Note that since the random factor is of finite extent (between $1/2$ and $3/2$), packets are guaranteed to eventually be sent. However, the result is an average increase in the interval between RTCP packets.

The behavior of unconditional reconsideration differs during the initial transient as well. Consider $N$ users who simultaneously join the group at time 0. They all schedule their first RTCP packets to be sent between $t = 1.25$ and $t = 3.75$. The users whose packets were scheduled earliest (at a time a little bit after $t = 1.25$) will not reconsider with conditional reconsideration, and will always send their packets. This is because no one else has sent any packets yet, and thus they have not perceived the group size to have changed. In fact, because of network delays, many users may send packets without reconsidering. Once the first transmitted packet has reached the end systems, conditional reconsideration "kicks in", since users will perceive a change in group size only then. With unconditional reconsideration, those first few users do not wait for the first packet to arrive before using the reconsideration algorithm. They will all recompute the timer. Obviously, the group size estimate hasn't changed, but the random variable will be redrawn. For the first few users, the random factor was initially extremely small (that's why they are the first few users to send). In all likelihood, when the factor is redrawn, it will be larger than the initial factor, and thus the resulting interval will be larger. This will delay transmission of RTCP packets for those users. As time goes on, it becomes less likely than the new random factor will be greater than the initial one. However, by then, any RTCP packets which may have been sent will begin to arrive, increasing the group size estimates for each user. In this fashion, unconditional reconsideration alleviates the initial spike of packets which are present in conditional reconsideration. These arguments are all quantified in later sections.

Both modes of the algorithm are advantageous in that they do not require any modifications to the current RTCP protocol structure. In fact, they operate properly even when only a subset of the multicast group utilizes them. As more and more members of a group use the algorithm, the amount of congestion is lessened in proportion. This leaves open a smooth migration path to the new version of the algorithm.

### 3.1 Simulations

We ran a number of simulations to examine the performance of the reconsideration algorithms.

In our simulation model each user is connected to the network via an access link of 28.8 kb/s downstream (i.e., from the network to the user). We assume upstream links are infinitely fast, since congestion occurs only downstream. This congestion is due to the RTCP reports from all of the other users being sent to any particular user. Multicast join latencies are ignored; this is reasonable in protocols such as DVMRP [16] since initial packets are flooded. We assume that the network introduces a delay of $D$ seconds, where $D$ is uniformly distributed between 0 and 600 ms. Each user has a 100 kB buffer on the downstream access link. We assume all RTCP packets are 128 bytes in size.

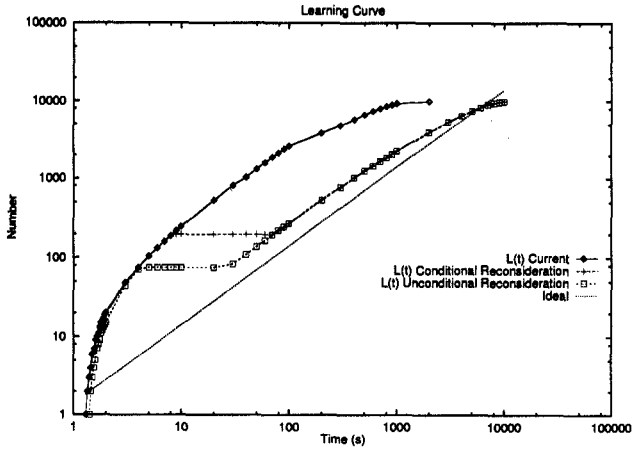

Figure 1: Learning Curve, step join with $N$=10,000

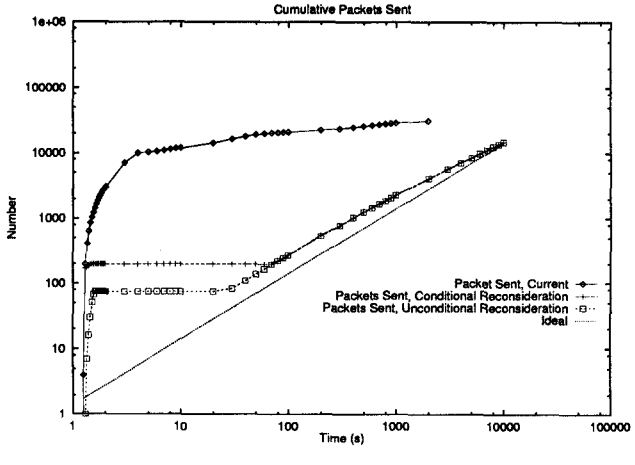

Figure 2: Total Packets Sent, step join with $N$=10,000

Figure 1 and Figure 2 depict state evolution for a single user when 10,000 users simultaneously join a multicast group at $t = 0$. The figures depict the system with no reconsideration (the current specification), conditional reconsideration, unconditional reconsideration, and the ideal behavior. The graphs are plotted on a log-log scale to emphasize the beginning and complete evolu-

tion of the system. Figure 1 depicts the learning curve, and Figure 2 shows the integral of $r(t)$, i.e., the total number of packets sent, given that $r(t)$ is the packet transmission rate to the multicast group. Note the burst of packets sent in the beginning by the current algorithm. Exactly 10,000 packets are sent out in a 2.5 s interval. This is almost 3000 *times* the desired RTCP packet rate. However, this burst is reduced *substantially* by the reconsideration mechanisms. Conditional reconsideration causes only 197 packets to be sent over a 210 ms interval, and unconditional reconsideration causes merely 75 packets to be sent over a 327 ms interval. We also observed similar improvements with a variety of different link speeds, delays, and group memberships.

We noted that the startup burst with reconsideration was particularly disturbing when network delays were deterministic instead of uniformly distributed. This is demonstrated in Figure 3, which looks at the cumulative number of packets sent when $10,000$ users simultaneously join at $t = 0$, using conditional reconsideration. In all cases, the mean network delay was 300ms, but the distribution varies. Exponentially distributed network delays exhibited nearly identical performance to a uniform distribution. Later sections will demonstrate that the spike is dependent on the amount of time until the first packet arrives. As the number of users in the step join becomes large, the number of users who send their packets within the first $\epsilon$ seconds after $t = 1.25$ grows large for any $\epsilon$. Consider an $\epsilon$ much smaller than typical network delays, say 10 $\mu$s. As far as computing arrival times at end stations, these packets can be treated as though they were all sent at the same time. The amount of time until the first of these packets arrives at any end system is thus the *minimum* network delay experienced by all of those packets. If the network delays are exponential, the expected minimum of $N$ exponential random variables goes to zero as $N$ grows. The same is also true for a uniform random variable. For a deterministic variable, this is not the case; the minimum is always the same. Therefore, the performance is worse for network delays which are fixed.

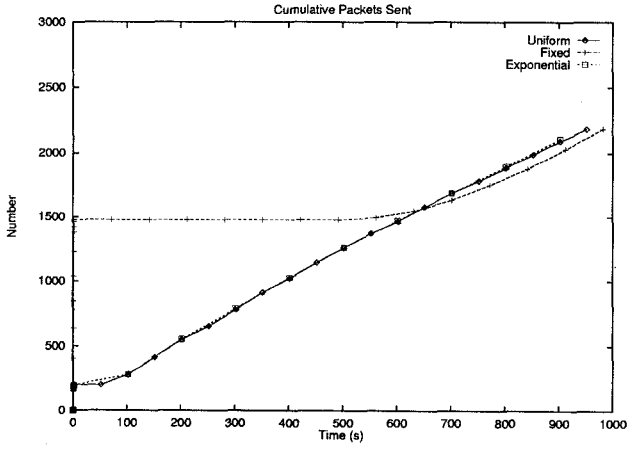

Figure 3: Effect of Delay Distribution on Transient for Conditional Reconsideration

We have also observed that the reconsideration mechanisms cause a complete pause in packet transmissions after the initial spike. This pause (which we call the "plateau effect") lasts for a time proportional to the number of packets in the spike. This has both positive and negative implications. On the plus side, it gives network buffers time to clear. However, it also causes the send rate to deviate from our desired fixed $1/C$ packets per second. The phenomenon occurs because the spike of packets in the beginning causes the system to reconsider, and not send, all packets after the spike. A more detailed explanation of the phenomenon is given in Section 4. However, after the spike and plateau, the packet rate behaves fairly well, sending packets at a nearly constant rate.

We also ran simulations to observe performance in linear joins, where groups of users join the system at times $\Delta$ seconds apart, for some small $\Delta$. The results are shown in Figure 4 and Figure 5. Both plots depict the cumulative number of packets sent by all users. The simulation parameters are identical to the above cases, except network delays are deterministic 300 ms. The first plot depicts conditional reconsideration, and the second, unconditional. In all cases, 2500 users join the system, but the rate that they do so is varied. Both plots depict the step join, and joins at a rate of 5000, 2500, and 500 users per second. The plots indicate that linear joins quickly eliminate the initial transient of packets and the plateau period, with the reduction being better for unconditional reconsideration.

We have done some analysis to examine how the behavior of reconsideration changes under linear joins. Our analysis has shown that as soon as the number of users who join, times $\Delta$, exceeds the network delays, the initial bursts in the reconsideration algorithms begin to disappear, whereas they remain for the current specification. All other aspects of the system performance (including long term growth of $L(t)$) are identical to the step-join case.

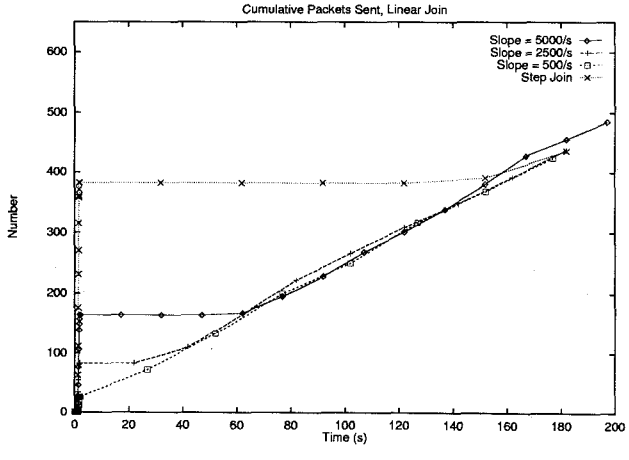

Figure 4: Linear Joins: Conditional Reconsideration

## 4 Analysis

In this section, we present a mathematical analysis of the reconsideration mechanism. We first consider the case where there are no network delays. This results in a differential equation which describes the learning curve. The analysis also applies to networks with delay, but only models the post-transient behavior of the system. However, this is sufficient to compute the post-transient packet rate and system convergence times. We then extend this analysis to the case of network delays, and derive ex-

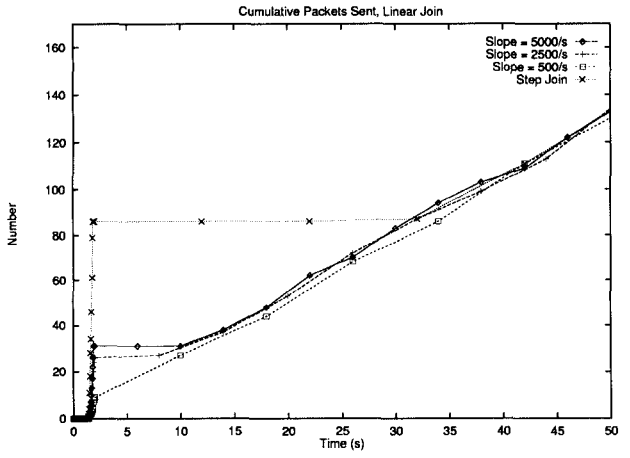

Figure 5: Linear Joins: Unconditional Reconsideration

pressions which describe the transient spikes and plateaus in the learning curve. We also analytically demonstrate the reasons for improved performance from unconditional reconsideration, which only exist in the presence of network delays.

### 4.1 No Delay

We consider a system where all of the users join the network at the same time, $t = 0$. It is assumed that the network introduces neither delay nor loss, and that access links have infinite bandwidth. The result is that when a user sends an RTCP packet, it is received by all of the users simultaneously at the time it was transmitted.

In the model considered here, all users will have exactly the same state (in terms of $L(t)$) at all times. Thus, we trace state evolution as seen by a particular user. The user estimate has converged when $L(t) = N$, the number of users actually in the group. Our model also assumes a fluid behavior for packet arrivals, as in [17], so that $L(t)$ is a continuous variable.

Whenever a packet is reconsidered, it is either sent, or it is not, depending on whether the newly computed send time is before or after the current time. We can therefore view the reconsideration mechanism as causing any packet to be sent with some probability $P$. In the most general case, $P$ is a function of the current time $t$, the time of the last RTCP report, and the number of users observed at $t$, $L(t)$. Fortunately, the learning curve is only affected by packets which are initial, that is, sent by users which have not yet sent a packet. For all such users, the last report time is initialized to $t = 0$, so that the send probability is a function of $t$ and $L(t)$ only.

If we consider some small interval of time, the change in $L(t)$ is equal to the number of initial packets scheduled to be sent during this interval, times the probability of sending a packet in that interval. Based on this, we can immediately write the differential equation:

$$\frac{dL}{dt} = d(t)P(t, L(t)), \tag{2}$$

where $d(t)$ is the rate of packets scheduled for transmission during some time interval. What remains is the evaluation of the scheduled rate $d(t)$ and probability $P(t, L(t))$. We first consider the send probability.

Consider an initial packet scheduled to be transmitted by a user at time $t$. Since the number of perceived users, $L(t)$ has surely changed over any time interval, this packet is reconsidered [2]. At time $t$, the user perceives $L(t)$ other users in the system. It thus calculates a new packet interval, which is equal to:

$$T = R(\alpha)\max(T_{\min}, CL(t))$$

Since $CL(t)$ is larger than $T_{\min}$ most of the time, we ignore the max operator. Keeping in mind that the previous report time is always $t = 0$, we can immediately write the probability of sending a packet using Equation (1):

$$P_{\text{send}} = \frac{t-(1-\alpha)CL(t)}{2\alpha CL(t)} \quad (1-\alpha)CL(t) < t < (1+\alpha)CL(t) \tag{3}$$

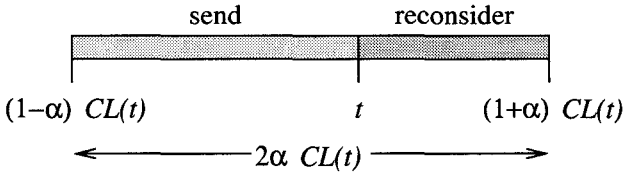

Figure 6: Computing $P_{\text{send}}$ with reconsideration

The numerator represents the range of times in the interval widow which fall below the current time $t$, while the denominator represents the total range over which the times for the interval are selected. This is illustrated in Figure 6. Note that this probability only makes sense when $t$ is between $(1-\alpha)$ and $(1+\alpha)$ of $CL(t)$. When $t$ is to the left of the reconsideration window, the probability is zero, and when $t$ is to the right of the window, it is one.

An important implication of this equation is that the send probability is zero when $t < (1-\alpha)CL(t)$. This places an upper bound on the learning curve; if the learning curve should reach this bound, no initial packets would be sent, and the curve would remain flat until it fell back below this upper bound. We therefore define the *maximum learning curve* $L_{\max}(t)$ to be:

$$L_{\max}(t) = \frac{1}{(1-\alpha)C}t \tag{4}$$

The actual learning curve $L(t)$ is always below $L_{\max}(t)$.

The next step is to compute the scheduled rate, which is significantly harder. In the ideal case, the rate that packets have been scheduled at should equal the number of users in the system, $N$, divided by the average RTCP interval size perceived by those users at time $t$, namely $CL(t)$. At any point in time the fraction of packets to be sent which are initial is $(N - L)/N$. Thus, the scheduled rate of initial packets is roughly given by:

$$d(t) = \frac{N - L(t)}{CL(t)}$$

The curves of Figure 1 show that the reconsideration algorithms exhibit linear behavior between roughly $t = 100$ and $t = 9000$

[2] It is for this reason that we make no distinction between conditional and unconditional reconsideration here

(thus ignoring the transient behavior in the beginning few seconds). We therefore attempt to determine the slope $a$ of this line based on the differential equation. Substituting $L(t) = at$ into (2):

$$a = \frac{N - L(t)}{CL(t)} \frac{1 - (1-\alpha)Ca}{2\alpha Ca}$$

For small $t$, $L(t) < N$, so we can ignore the $L$ in the first term's numerator. Thus:

$$\frac{2\alpha C^2 L(t)}{N} a^2 + a(1-\alpha)C - 1 = 0$$

Thus, for large $N$ and small $t$, $L(t) \ll N$, and we can neglect the $a^2$ term, and obtain the desired result:

$$a = \frac{1}{(1-\alpha)C} \tag{5}$$

Not coincidentally, this is also the slope of the maximum learning curve. The equation indicates, therefore, that $L(t)$ grows at its maximum rate until the approximation is no longer valid, at which point its growth tapers off.

As mentioned previously, the equation for the scheduled rate $d(t)$ is very approximate. We have done some more extensive analysis, and found that a slightly better approximation is given by:

$$d(t) = \frac{N - L(t)}{C\frac{1-\alpha}{2-\alpha}L(t)} \tag{6}$$

This is of the same form as the previous equation, but tends to model the nonlinearities of the system better.

Now, with the density and send probabilities computed, we can write the final differential equation, which is:

$$\frac{dL}{dt} = \frac{N - L(t)}{C\frac{1-\alpha}{2-\alpha}L(t)} \frac{t - (1-\alpha)CL(t)}{2\alpha CL(t)}$$

This ODE allows us to compute a numerical solution, which can be compared against the simulations. Figure 7 shows the learning curve, with 10,000 users joining at $t = 0$, for both analysis and simulation. In the simulation, however, we take into account non-zero delays and finite link speeds; network delays are a deterministic 300 ms, and link speeds are 28.8 kbps. Note that despite this change in assumptions, the analytical expression *still* comes extremely close to the simulations for a large portion of the convergence period. In particular, it is very close during the period of linearity of $L(t)$ and less accurate afterwards. In addition, the differential equation does not capture the behavior of $L(t)$ for $0 \leq t \leq 20$, where the simulated curve exhibits the spike and plateau (this is difficult to see in Figure 7 because of the x axis scale).

We believe that network delays only impact the behavior of $L(t)$ when they are on the order of $CL(t)$. This is somewhat intuitive; the timescale of transmission events for any particular user is $CL(t)$. If network delays are much smaller than this, they are almost instantaneous as far as sending packets goes, and therefore do not affect the system behavior. It is for this reason that network delays only impact the learning curve during the first minute or so.

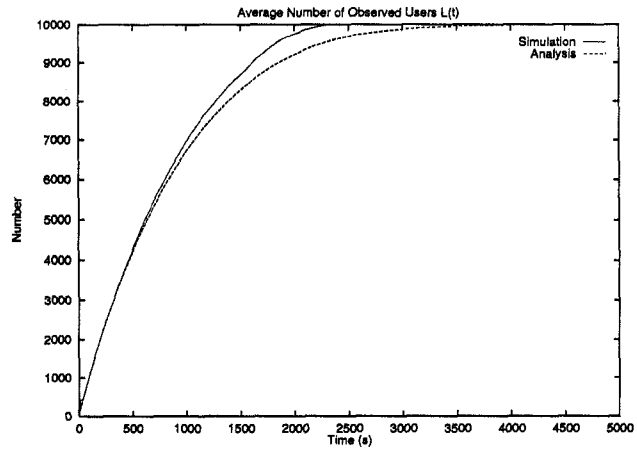

Figure 7: Simulated vs. analytical learning curve

With an understanding of the behavior of $L(t)$, we are now in a position to discuss the real quantity of interest; the aggregate bit rate generated by these sources as they move towards convergence. We call this quantity $r(t)$. Since the integral of this quantity is the total number of packets sent, we have, as an immediate consequence:

$$r(t) \geq \frac{d}{dt} L(t)$$

Experimentally, we have observed that $r(t)$ is actually *equal* to the derivative of $L(t)$ for a large fraction of the time until convergence. The reason for this is that the reconsideration mechanism favors packets from users who have not yet sent a packet (initial packets). Consider two packets, both scheduled to be sent at some time $t$. One is an initial packet, and the other is from a user who has sent a packet previously. For the initial packet, the last report time is at $t = 0$, whereas for the other packet, the last report time is at some time $t^*$, not equal to zero. In the latter case, the bottom edge of the interval window is at $t^* + C(1-\alpha)L(t)$. Thus, the probability of sending a non-initial packet at time $t$ is:

$$P_{\text{sendold}} = \frac{t - t^* - C(1-\alpha)L(t)}{2\alpha CL(t)} \tag{7}$$

This quantity is *always* less than the send probability for initial packets as given in (3). In fact, for small $t$, $L(t)$ is equal to $t/C(1-\alpha)$. Plugging this in to (7), we get that the numerator of the fraction is negative, so the send probability is exactly zero.[3]. Therefore, $r(t)$ is exactly equal to the derivative of $L(t)$ while $L(t)$ is linear. We expect it to continue to track the derivative closely even as $L(t)$ tapers off.

Once $L(t)$ has converged to $N$, packets are sent at a rate of $1/C$ with conditional reconsideration. With unconditional reconsideration, this rate is somewhat less. Therefore, $r(t)$ exhibits a dual-constant behavior; it starts at $1/(1-\alpha)C$, stays there for some time, then reduces to $1/C$, where it remains from then on.

[3]Note that plugging in $L(t) = t/C(1-\alpha)$ to equation (3) yields a numerator of zero, and thus a probability of zero also. In fact, the send probability is zero only in the limit for $N = \infty$; it is slightly positive for all real cases. This is in contrast to the send probability for non-initial packets, which is exactly zero for finite N.

The final step is to approximate the convergence time. Unfortunately, the precise time depends on the non-linear regime of $L(t)$, which we cannot capture adequately. However, we can bound the convergence time by assuming linear behavior until $L(t)$ equals $N$. Since the actual $L(t)$ is less than this curve, the convergence time $T_c$ is easily bounded on the left by:

$$T_c \geq NC(1-\alpha)$$

This bound grows linearly with the group size, as expected.

It is possible to compute an upper bound as well. Consider the last initial packet to be sent. Before it is sent, $L(t) = N-1$. As long as the send probability is less than one, it is possible that this last initial packet will not be sent. But, according to (3), the send probability is one when $t > (1+\alpha)CL(t)$. This means that the last initial packet must be sent as soon as $t = (1+\alpha)C(N-1)$. This gives us an upper bound of:

$$T_c \leq NC(1+\alpha)$$

### 4.2 Modeling Delay and Loss

In this section, we consider the reconsideration algorithm in the presence of network delay and link bottlenecks. We compute the size of the spike during the initial transient, and the duration of the plateau. We also demonstrate the superiority of unconditional reconsideration in reducing these startup effects.

The spike and plateau are easily explained. At $t = 0$, all $N$ users join the system. They schedule their packets to be sent between $(1-\alpha)T_{min}$ and $(1+\alpha)T_{min}$. At time $(1-\alpha)T_{min}$, packets begin to be sent. Lets say the network introduces a delay of $D$ seconds. This means that no packets will arrive at any end system until time $(1-\alpha)T_{min} + D$. During these $D$ seconds, many packets will be sent by end-systems, causing the initial spike of packets. After $D$ seconds, this burst of packets will arrive. This causes a sharp increase in the perceived group size $L(t)$. This, in turn, increases the packet transmission interval, and moves the left hand side of the interval window well beyond the current time, so that $P_{send} = 0$. The result is a complete halt in transmissions until real time catches up with the left hand side of the reconsideration window.

This qualitative description of the system is easily quantified. For a large enough $N$, the flood of packets starting at time $(1-\alpha)T_{min}$ will saturate the access links $D$ seconds later, independent of whether conditional or unconditional reconsideration is used. While the links remain saturated, packets arrive at a continuous rate at the link speed, which we denote as $m$ packets per second. We can therefore express the arrival time of the $n^{th}$ packet as:

$$t_n = (1-\alpha)T_{min} + D + \frac{n}{m} \tag{8}$$

Since each packet arrival increases $L(t)$ by one, we can set $n$ equal to $L(t)$ in the above equation and solve for $L(t)$:

$$L(t) = m(t - (1-\alpha)T_{min} - D) \tag{9}$$

This flood of packets will cause the learning curve $L(t)$ to advance very quickly, beyond its maximum as given in (4). When the learning curve exceeds this maximum, all sending will stop. Call this stopping time $t_{stop}$. It can be obtained as the solution to:

$$(1-\alpha)CL(t_{stop}) = t_{stop} \tag{10}$$

Plugging in 9:

$$t_{stop} = (1-\alpha)T_{min} + D + \frac{(1-\alpha)T_{min} + D}{(1-\alpha)Cm - 1} \tag{11}$$

We can then plug this back into (9) and solve for the number of packets which have arrived at this point, $n_{stop}$:

$$n_{stop} = \frac{(1-\alpha)T_{min} + D}{(1-\alpha)C - 1/m} \tag{12}$$

The next step is to determine the number of packets sent up to this point. This quantity differs based on whether the reconsideration mechanism is conditional or unconditional. We first look at conditional.

The number of packets sent consists of two terms. Before the arrival of the first packet (at time $(1-\alpha)T_{min} + D + 1/m$), all packets scheduled to be sent are actually sent, since no users have observed a change in the group size (which would activate the reconsideration mechanism). The number of packets sent is then the rate of packets scheduled to be sent (which is $N/2\alpha T_{min}$) times the amount of time until the first packet arrives. We call this quantity $ns_c^1$ (the $c$ is for conditional, and 1 is for the first term):

$$ns_c^1 = \frac{N}{2\alpha T_{min}}\left(D + \frac{1}{m}\right) \tag{13}$$

Once the first packet arrives, reconsideration kicks in, and not all packets will be sent. Each will be sent with some probability, $P$. Unfortunately, this is not the same probability $P_{send}$ as defined in Equation 3. That equation ignored the max operator, assuming $L(t)$ was large most of the time. This is not true in the very beginning, where it takes a few packets to increase $CL(t)$ beyond $T_{min}$. We assume that once enough packets have arrived to do this, the result will be to move the left hand side of the reconsideration window ahead of the current time (this is true when $D < C$). In other words, we assume the left hand side of the reconsideration window is always at $(1-\alpha)CT_{min}$ until $t_{stop}$.

With this in mind, the send probability between the arrival of the first packet, and the stopping of transmission, is given by:

$$P = \frac{t - (1-\alpha)T_{min}}{2\alpha T_{min}} \tag{14}$$

The number of packets sent is given by the integral of the scheduled packet rate times the send probability:

$$ns_c^2 = \int_{(1-\alpha)T_{min}+D+1/m}^{t_{stop}} d(t)P\,dt \tag{15}$$

Since the scheduled rate is $N/2\alpha T_{min}$ during this time period of interest, the number of packets sent is obtained by:

$$ns_c^2 = \int_{(1-\alpha)T_{min}+D+1/m}^{t_{stop}} \frac{N}{2\alpha T_{min}} \frac{t - (1-\alpha)T_{min}}{2\alpha T_{min}} dt \tag{16}$$

This integral results in a growth in the number of sent packets as $t^2$ until complete cutoff at $t_{stop}$. The solution to the integral is:

$$ns_c^2 = \frac{N}{8\alpha^2 T_{min}^2}\left(\left(\frac{(1-\alpha)T_{min}+D}{(1-\alpha)Cm-1} + D\right)^2 - \left(D + \frac{1}{m}\right)^2\right) \tag{17}$$

And the total number of packets sent, using conditional reconsideration, during this transient spike is:

$$ns_c = ns_c^1 + ns_c^2 \tag{18}$$

These analytical results are compared with simulation in Figure 8. The figure displays the cumulative number of packets sent for a step join. For the simulation, 100,000 users join the system at $t = 0$. Network delays are deterministic and equal to 300 ms, and link speeds are 28.8 kbps. The plot shows only the initial transient. The linear and then $t^2$ behavior is clear from the simulation. Our approximation for both $ns_c^1$ and $ns_c^2$ is quite good. The analysis also predicts that sending will stop at $t_{stop} = 1.72s$, which agrees with the simulation. Also note that the number of packets sent is dominated by the $ns_c^1$ term.

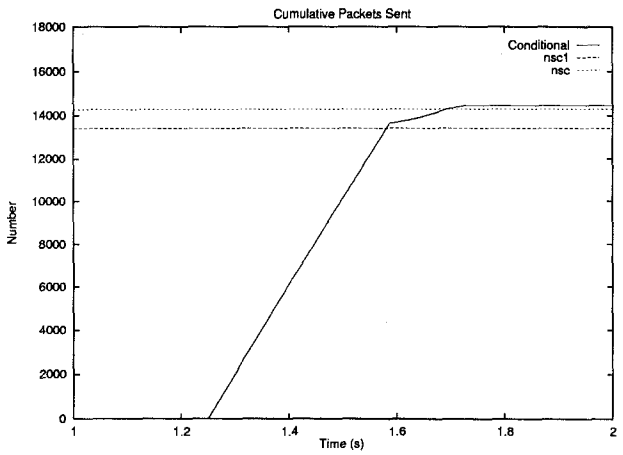

Figure 8: Transient with Conditional Reconsideration

For unconditional reconsideration, the number of packets sent during the transient is different. In the conditional case, the total consisted of two parts; one before the arrival of the first packet (as the reconsideration mechanism had not "kicked in" yet), and one after. In the case of unconditional, we do not need to wait for the arrival of a packet for the mechanism to activate. Therefore, the number of packets sent is given by an equation similar to that for $ns_c^2$ above. It is the integral of the scheduled rate, times the send probability. In this case, the integral is between $(1-\alpha)CT_{min}$ and $t_{stop}$, instead of just between the arrival of the first packet and $t_{stop}$. The number of packets sent for unconditional is therefore:

$$ns_u = \int_{(1-\alpha)T_{min}}^{t_{stop}} \frac{N}{2\alpha T_{min}} \frac{t-(1-\alpha)T_{min}}{2\alpha T_{min}} dt \tag{19}$$

Solving, we obtain:

$$ns_u = \frac{N}{8\alpha^2 T_{min}^2} \left( \frac{(1-\alpha)T_{min} + D}{(1-\alpha)Cm - 1} + D \right)^2 \tag{20}$$

This quantity is small compared to $ns_c^1$ for conditional reconsideration, thus the improved performance. These results are compared with simulation in Figure 9. The simulation model is identical to that in Figure 8, except unconditional reconsideration is used. As the plot indicates, only the $t^2$ behavior is present here.

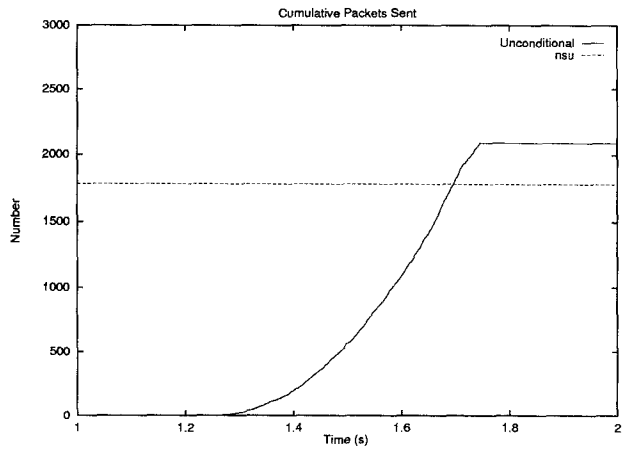

Figure 9: Transient with Unconditional Reconsideration

The total number of packets sent during the transient is much reduced, and reasonably well predicted by our analysis.

The next step is to determine the duration of the plateau period. Packet sending will start again when the current time catches up with the left hand side of the interval window, which will have quickly advanced to $(1-\alpha)Cns_c$. The time at which this happens, $t_{start}$ is (for conditional reconsideration):

$$t_{start} = (1-\alpha)Cns_c \tag{21}$$

If we assume $ns_c \approx ns_c^1$, we obtain:

$$t_{start} = \frac{C(1-\alpha)N}{2\alpha T_{min}} \left( D + \frac{1}{m} \right) \tag{22}$$

The duration of the plateau period itself is given by:

$$T_{plat} = t_{start} - t_{stop} \tag{23}$$

## 5 Summary and Future Work

RTP was meant to support real-time communications ranging from two-party telephone calls to broadcast applications with very large user populations. It incorporates an adaptive feedback mechanism that allows scaling to moderately sized groups, but shows a number of deficiencies once the group size exceeds on the order of a thousand. The problems can be summarized as congestion, convergence delays and state storage problems. We have solved the congestion problem via a simple algorithm called reconsideration. Both analysis and simulation have shown that the algorithm reduces the initial congestion by orders of magnitude under a variety of conditions. Furthermore, the algorithm is backwards compatible with the existing RTCP algorithm, allowing for a simple migration path.

The reconsideration algorithm has been implemented as part of a generic RTP Library, and is now operational in several common Mbone tools, such as rat and Nevot. It has also been proposed to the IETF as an improvement to the RTP specification, and is likely to be incorporated into the next release.

Future work involves considering the problem of simultaneous leaves, and resolving the other RTP scalability problems: state storage and delay.

## 6 Acknowledgments

The authors wish to thank Steve Casner, T.V. Lakshman, Sanjay Mithal, Daniel Rubenstein, Bernhard Suter, and Don Towsley for their insightful comments and discussion.
